

MARZ: MANUAL AND AUTOMATIC REDSHIFTING SOFTWARE

S. R. HINTON^{1,2}, T. M. DAVIS^{1,2}, C. LIDMAN^{2,3}, K. GLAZEBROOK⁴, AND G. F. LEWIS⁵

Draft version November 23, 2015

ABSTRACT

The Australian Dark Energy Survey (OzDES) is a 100-night spectroscopic survey underway on the Anglo-Australian Telescope using the fibre-fed 2-degree-field (2dF) spectrograph. We have developed a new redshifting application MARZ with greater usability, flexibility, and the capacity to analyse a wider range of object types than the RUNZ software package previously used for redshifting spectra from 2dF. MARZ is an open-source, client-based, Javascript web-application which provides an intuitive interface and powerful automatic matching capabilities on spectra generated from the AAOmega spectrograph to produce high quality spectroscopic redshift measurements. The software can be run interactively or via the command line, and is easily adaptable to other instruments and pipelines if conforming to the current FITS file standard is not possible. Behind the scenes, a modified version of the AUTOZ cross-correlation algorithm is used to match input spectra against a variety of stellar and galactic templates, and automatic matching performance for OzDES spectra has increased from 54% (RUNZ) to 91% (MARZ). Spectra not matched correctly by the automatic algorithm can be easily redshifted manually by cycling automatic results, manual template comparison, or marking spectral features.

1. INTRODUCTION

The Australian arm of the Dark Energy Survey (OzDES) is a five-year, 100-night spectroscopic survey using the Anglo-Australia Telescope (AAT), and aims to provide accurate spectroscopic redshifts of Type Ia supernova hosts, photo-Z targets, emission line galaxies (EML) and radio galaxies between redshift ranges of $0.1 \leq z \leq 1.2$, in addition to spectroscopic measurements of active galactic nuclei and quasars in the redshift range of $0.3 \leq z \leq 4.5$ Yuan *et al.* (2015). A close collaborator with OzDES is the newly formed 2dFLenS survey⁶ which aims to measure redshift-space distortions over 985 square degrees in its 50-night spectroscopic survey using with AAT. The process of extracting redshifts from spectroscopic measurements is thus required to be robust across a wide variety of target types, and since our aim is primarily to acquire redshifts, our survey will be most efficient when we can extract redshifts from low signal-to-noise spectra. In addition to this, the OzDES survey will target a large number of AGN spectra using stacked observations, making effective quasar redshifting a necessary requirement in the utilised software.

Given the above motivation, we drew a set of minimum requirements a modern software replacement would need to satisfy:

1. The automatic matching has to be more accurate and reliable than that from RUNZ.

2. The interface should be intuitive to allow fast manual checking and correction or verification by the user.
3. The software should be easy to install, operating system independent, and be able to be updated without user prompting.

This paper will detail the how the MARZ software satisfies the above requirements, explain the matching algorithm utilised by the program, and provide relevant information on how to access and use the software, in addition to what data input it handles.

2. PRIOR SOFTWARE

A variety of redshifting solutions have been previously developed, with much of the developed software being spectrograph or survey specific. A large amount of prior redshifting software is descendent from the cross correlation algorithms implemented by Tonry and Davis (1979), in which they digitalised the analog techniques used by Griffin (1967). The software utilised previously by the OzDES team, RUNZ, was originally written for use by the 2dF galaxy redshift survey (Colless *et al.* 2001), and was modified by Saunders *et al.* (2004) for use in the WiggleZ survey. It is primarily against this modified version of RUNZ that we compare results to in this report. Unfortunately, there are several reasons why neither the RUNZ software package, nor other available redshifting software packages, were sufficient for use in the OzDES survey. The foremost problem with using the existing software solution was the inclusion of more varied target object types at a lower signal-to-noise ratio than prior surveys, and the resulting decrease in automatic matching capacity by the legacy software created an undesirable workload for the members of the OzDES team to manually redshift observed spectra. Additionally, the legacy nature (fortran, pgplot, cshell, and figaro and starlink libraries) of the RUNZ code base makes code updates difficult, installation and usage

complicated, especially for new users faced with having to compile, install and learn the software. The sum of these factors prompted a search for alternative software, leading to the development of a modern software replacement.

The main alternative considered was the popular RVSAO 2.0 software package, which utilises cross correlation techniques, in addition to providing feature matching capacity (Kurtz and Mink 1998). Unfortunately, the software operates only in command line and without any interactive user input. The 2010 release of the *xcsao* program (the cross correlation matching algorithm in RVSAO 2.0) takes up to 67 input parameters (Mink 2010), which, whilst allowing great specificity in redshifting, introduces technical overhead to cosmology groups attempting to use the software. Due to this, and the lack of modern interface, this software did not satisfy OzDES’s requirements.

As of the eighth data release (DR8) of the Sloan Digital Sky Survey (SDSS), the redshifting software used in their survey utilises a minimum χ^2 algorithm (Aihara *et al.* 2011). Prior to DR8, a cross correlation algorithm was used (Adelman-McCarthy *et al.* 2008), where the same results were found when matching using the different methods for 98% of spectra Aihara *et al.* (2011). Similarly, this potential software system also does not satisfy the OzDES requirement of easy manual redshifting and confirmation, which is required by OzDES due to the low signal-to-noise strength in observed spectra.

Finally, the GAMA survey utilises the AUTOZ code for redshifting low-redshift galaxy and stellar spectra (Baldry *et al.* 2014) by cross correlating input spectra with a range of templates. The IDL code does not feature an interface, however the algorithm utilised outperformed the RUNZ algorithm for all spectra types barring quasar spectra. Due to the dependence on IDL and lack of an interface, the AUTOZ software did not meet the OzDES requirements.

Given prior software was unable to satisfy all OzDES requirements, new software was developed.

3. PLATFORM

We chose to implement the matching software as a web application, since this allows access to the software from any laptop or desktop with an internet connection with no installation. The interface utilises Google’s AngularJS⁷ framework for its application scaffold, as AngularJS allows dynamic two-way binding between interface and application variables for easy user interface creation, easy server communication, and has a vast amount of existing resources publicly available.

To supplement AngularJS and allow rapid prototyping, existing interface element libraries were imported to reduce the amount of reimplementing of common elements and boilerplate code required to produce a

functioning application. To this end, Angular UI’s Bootstrap⁸ reimplementation of Twitter’s Bootstrap⁹ components was added to the project code base, to allow both the functionality of AngularJS and rapid prototyping of using Bootstraps pre-made components.

Data processing in browsers has only recently become possible due to HTML5’s Web Worker API,¹⁰ which allows for multi-threaded processing by sending tasks to independent workers. Communication to Web Workers and any future potential server communication will use JSON (JavaScript Object Notation) format (Bray 2014), and will conform to the REST (Representational State Transfer) interface (Windley 2005) to allow for easy end-point construction. This also has the benefit of making all messages human-readable and able to be linked to web services easily due to existing support in all modern server frameworks.

The local application state is preserved via utilisation of local storage, where local state is preserved in JSON format. This gives the benefit that results are not lost when exiting the application or refreshing the browser, negating one of the major disadvantages of stateful web applications. Changes to application are persisted via setting cookie properties instead of using local storage, so to provide a concrete demarcation between user preferences and user redshifting data.

The code base, named MARZ, is hosted publicly on GitHub¹¹, allowing for open issue management, feature requests, open collaboration, forking of the project and instant web-hosting.¹² **TALK ABOUT VERSION CONTROL WHEN IMPLEMENTED**

4. FITS FILE FORMAT

In this section, we detail the FITS file format that can be consumed by MARZ. The data extraction algorithm searches for extension names. Spectrum intensity is expected to be found in either the primary header data unit (HDU) or one named *intensity*. Spectrum variance is searched for using the extension name *variance*, and similarly the *sky* and *fibres* should contain the sky spectrum and details on the fibres respectively. As the primary use case of the software is with the AAOmega spectrograph (which uses 400 fibres at a time), the software can still be used for single spectra, either by omitting the fibres data or having only one row in the binary table. Whilst spectra can be viewed with only the intensity present, the matching algorithms require variance as well. The sky and fibre data is optional. The intensity and variance data should be present as images of $m \times n$ dimensions, where m is the number of pixels in the spectrum and n are the number of spectra in the file. The sky spectrum can take on a similar $m \times n$ format, or simply be present in an array of length m , which loads the same sky spectrum for all spectra.

⁷ <https://angularjs.org/>

If the *fibres* extension exists, it should be as a binary table of n rows. MARZ searches for the columns TYPE, NAME, RA, DEC, MAGNITUDE and COMMENT. Spectra marked with types other than ‘P’ are removed from analysis (so as to not analyse fibres used for sky subtraction or calibration), and spectra marked with the comment ‘PARKED’ are also removed. Priors can be enforced by specifying an object type in the comment field, and the effect of object type per template can be modified in the `templates.js`, where the property `weights` is used to map object types to numeric weights. These priors are used to increase or decrease the weight of specific templates for specific object types; as an example the type ‘AGN_reverberation’ is weighted to increase matching strength against the quasar template. In section 7, I compare the results of MARZ and RUNZ for low signal-to-noise data (both using weights), and compare performance for high signal-to-noise without weights for either MARZ or RUNZ.

MARZ does not require each intensity value to have a specific wavelength. The wavelength of the input spectra can be determined in multiple ways. MARZ will search for an image extension named *wavelength*, and if the extension exists, the image data will be loaded as wavelengths. The data can take an $m \times n$ format or simply be an array of length m (similar to the sky data). If the extension is not found, MARZ will check the primary header for cards with which to construct the wavelength array. The array is constructed such that a reference wavelength CRVAL1 (corresponding to pixel CRPIX1) with linear pixel separation (either CDEL1 or CD1_1) can be used to create a linear array of wavelength values. The wavelengths can be present in linear form (units of Angstroms), or if flag LOGSCALE is set in the primary header, wavelength values are taken to be $\log_{10}(\lambda)$, such that a pixel value of 3 would correspond to 1000Å. By default, MARZ assumes the wavelengths presented are taken in air and will thus shift them into a vacuum reference frame. If this has already been done, VACUUM can be set and MARZ will not vacuum shift the input wavelengths. The spectra is further assumed to have undergone heliocentric velocity correction.

Example FITS files can be downloaded on the *Usage* section of the MARZ application to provide file examples for the above specifications.

5. MATCHING ALGORITHM

The algorithm that takes an observed spectrum and measures the redshift is the heart of any redshifting program. The matching algorithms in MARZ utilise a modified version of the AUTOZ algorithm implemented by Baldry *et al.* (2014). In light of the success of χ^2 algorithms in modern surveys (Bolton *et al.* 2012) an initial χ^2 algorithm was developed, but was consistently outperformed by the cross correlation algorithm and discarded. Performance of the χ^2 algorithm could be increased by improving normalisation between the template and input spectra, but this was too computationally intensive when implemented. FITS file input from the AAOmega spectrograph undergo two distinct steps of processing: (1) the preprocessing stage to clean

the data and (2) the matching process to align the observed spectra with template spectra, simultaneously finding the best-fit object type and shifting it to the best-fit redshift.

The preprocessing stage is designed to remove any bad pixels and cosmic rays from the data before being returned back to the interface, so that the user can manually redshift using the cleaned data.

- **Bad pixels** are defined when the intensity spectrum is NaN, negative or exceeds a certain configurable threshold, or if the variance spectrum for the pixel is negative.
- **Cosmic rays** are identified via second neighbouring pixels exceeding thirty standard deviations from the mean, with lower thresholds than 30σ often mistaking strong emission lines as cosmic rays.

Bad pixels have their intensity replaced with the mean to four pixels either side of the flagged pixel. Pixels flagged as a cosmic ray have a 9 pixel window (centered on the flagged pixel) replaced by a constant value, which is given by the mean intensity of pixels in a 19 pixel window (centered on the cosmic ray), discounting pixels in the cosmic ray. These pixel values were the minimum window found to produce sufficient quality means and remove the majority of cosmic rays.

The continuum is initially subtracted via the method of rejected polynomial subtraction, where a 6-degree polynomial is iteratively fitted to the spectrum and, as with AUTOZ, all points greater than 3.5 standard deviations from the mean are removed from the fitting process. As soon as an iteration discards no extra pixels, or after fifteen iterations (to ensure the final array of values is not excessively sparse), the loop is terminated and the final polynomial should closely follow the continuum, and is thus subtracted out.

This initial round of continuum subtraction is not intended to be high enough quality for the automatic matching process, it is done to give the user the option of manually redshifting spectra without continuum, allowing them to focus on the emission and absorption features of the spectrum without the broad shape of the continuum to distract. In order to limit the effect that singular emission features can have on spectrum matching, all features are clipped at a distance of 30 standard deviations from the mean. Unlike many redshifting programs, heliocentric corrections are not applied to the spectra as they are expected to have been applied already in the given spectra. This allows stacked spectra to be analysed through MARZ. OzDES stack spectra from multiple runs in order to build up signal-to-noise. Therefore the spectra have to be put a consistent wavelength solution prior to stacking, which means the heliocentric correction (which differs from night to night) must be done before the spectra are stacked.

The preprocessing algorithm detailed above takes an input intensity and variance spectrum, where the variance spectrum is typically computed in the data

Figure 1. The top subfigure shows an example input spectrum from which the continuum will be removed. The sixth degree fitted polynomial is shown dashed in this subplot, and the spectrum after subtraction of this polynomial fit is shown in the middle subplot, where we can see that broad continuum features are removed. The middle subplot also shows the output of the smoothed median filtering (dashed), and spectrum after subtraction of this filter is shown in the bottom subplot, where we can see even fine continuum detail has been removed from the spectrum.

Figure 2. The quasar processing steps illustrated. The top panel depicts in input spectrum intensity, with variance shown in red. The polynomial subtraction removes the almost constant continuum and is shown in the second panel from the top. The third panel shows the output after several steps, including an initial tapering of the spectrum, rolling point mean of the spectrum. The variance undergoes median filtering, boxcar smoothing and addition of minimal variance as described in text. The final spectrum after dividing the intensity by the variance is shown in the bottom panel. We can see that the spectrum is cleaner, is properly tapered, and emission features are accentuated.

pipeline using Poisson and readout noise. The output of the preprocessing algorithm is an adjusted intensity and variance spectrum, and this becomes the input of the matching algorithm. In the matching algorithm, MARZ first duplicates the intensity spectrum so that two copies exist internally. This is necessary because the matching of the broad-featured quasar template differs to matching of the other templates, and the copy of the intensity spectrum used for quasar matching shall now

be referred to as the quasar spectrum, and the other spectrum - used to match all other templates, shall be referred to as the general spectrum.

5.1. Quasar spectra

Departing from the AUTOZ algorithm, the quasar spectrum undergoes smoothing via a rolling-point exponential decay mean function of window width 7 pixels, with exponential decay factor of 0.9, such that each point be-

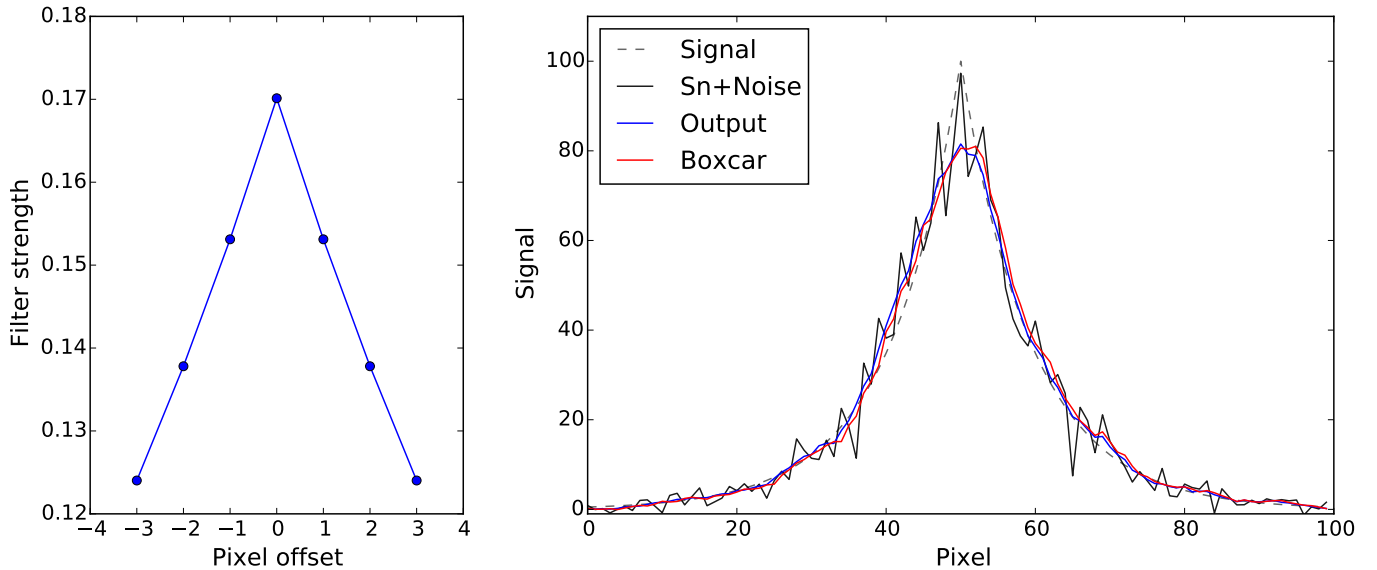

Figure 3. The left hand subplot shows the smoothing convolution filter used in MARZ on the quasar spectra. On the right hand side, the black dashed line represents an underlying signal, modelled as an exponential decay. Independent Poisson noise is added to this signal to give the algorithm input (shown in black), and the output of the convolution of this signal with the smoothing filter is shown in blue. We can see that, despite the occurrence of subpeaks, the original signal peak is recovered, unlike the peak discovered when using boxcar smoothing (a uniform convolution). This is due to the increased contribution at lower pixel separation, and increases the chance that a smoothed peak will be located at the same pixel in the noisy data.

comes

$$x_i = \left(\sum_{k=-3}^3 0.9^{|k|} \right)^{-1} \sum_{j=-3}^3 x_{i+j} 0.9^{|j|}, \quad (1)$$

where both the size of the window and strength of the exponential decay are not sensitive to small change. Pixel values were selected to maximise matching efficiency over test spectral data. This method of smoothing was selected and tuned so that the location of broad peaks remained unchanged whilst still providing sufficient smoothing of the spectrum to increase similarity to the template. This convolution is illustrated in Figure 3.

As we wish to preserve broad features found in quasar spectra, we require the quasar error spectrum to be sufficiently smooth that broad features are not destroyed when we apply the variance onto the spectrum intensity. A median filter of 81 pixel width is applied to the variance, and then the result is smoothed with boxcar smoothing using a window of 25 pixels. Pixel values were chosen to give optimal performance, though are not sensitive to small change so long as fine pixel detail is removed from the variance plot. In order to preserve even more broad shape by creating a more uniform variance that does not have the possibility of creating false features by having small variance, the variance of the spectrum is increased by addition of five times the minimum spectrum variance, where again the results are not highly sensitive to the amount of variance added. The quasar intensity is then divided by the adjusted variance to produce a spectrum that retains broad features and shapes, but down-weights sections of higher variance which are commonly observed at wavelengths close the end of spectroscopic CCD range. The loss of resolution entailed by the variance modifications detailed above results in any sharp emission lines present in

the spectrum to be more significant when compared to emission lines in the general spectrum, however the relative lack of sharp emission line features in the quasar template makes this issue not significant.

5.2. General spectra

As the sharp features of the general templates are enhanced by smoothing, the general spectrum is not smoothed. Instead, the spectrum undergoes a cosine taper, and then undergoes a second step of continuum subtraction, where a boxcar smoothed median filter (121 pixel window of boxcar smoothing and 51 pixel window median filter) is subtracted from the spectrum, with pixel values following AUTOZ and corresponding to a wavelength distance of 125 and 53 Angstroms respectively for typical AAOmega spectra. The cosine tapering of the spectrum ensures that features are not introduced at points of discontinuity at the ends of the spectrum in the case the input spectrum is zero-padded. This second step of continuum subtraction is not applied to the quasar spectrum, as the fineness of the smoothed median subtraction would result in broad features being completely removed from the spectrum. Figure 1 illustrates each step in this process, in addition to the original polynomial continuum subtraction.

The general spectrum then has error adjustment applied, where each pixel has its variance set to the maximal value of itself and the variance of its two neighbouring pixels. Following Baldry *et al.* (2014), this is to allow for uncertainty in the sky subtraction and any underestimation of errors next to sky lines. The variance spectrum is then widened again, where each pixel is set to a maximum of its original value or 70% of a thirteen pixel median filter, which serves to remove from the variance any points of sufficiently low variance that

division of the intensity by the variance would create a fake emission feature. Numerical values chosen mirror those used in the GAMA survey. The intensity of the general spectrum is divided by the variance spectrum to down-weight pixels with higher uncertainty.

Figure 4. The probability of MARZ assigning a suggested quality differentiated by the quality assigned by a human redshifter. Importantly, a QOP1 spectrum and a QOP2 spectrum respectively have a 0.8% and 1.4% chance of being classified as a QOP4 spectra. However, these mismatches are primarily due to errors in the data reduction process which introduce false features. From the data analysed, 37% of actual QOP4 spectra are classified as QOP3, where the automatic QOP algorithm has assigned a lower value due to the presence of a strong secondary peak in the cross correlation values, an occurrence illustrated in Figure 6.

5.3. Quasar and general spectra

Both the general and the quasar spectrum undergo cosine tapering and root-mean-square normalisation, the former to remove ringing in a Fourier transform (apodization; Kurtz and Mink 1998), with pixel width following AUTOZ but insensitive to change, and the latter to ensure comparable cross correlation values between different templates. The spectra are oversampled and then Fourier transformed. The quasar spectrum’s transformation is then cross correlated with the quasar template, and all other templates are cross correlated with the general spectrum. Cross correlation results are then inverse transformed, with the inverse transformed array representing cross correlation strength over a redshift range. Peaks within allowed redshift ranges for each template are selected, and if prior information on the object type is accessible in the FITS file, the peaks for each template are then weighted. Peaks from all templates are then sorted together, and the ten highest correlation value peaks have a quadratic fit applied around the peak for sub-pixel determination of local maxima. The sub-pixel location of the peaks are converted into a redshift value, and these are returned to the user, with the highest peak representing the best automatic matching found. A po-

tential quality is returned to the user, which is a function of the cross correlation strength of the two greatest peaks, v_1 and v_2 respectively. These peak values are used to construct a Figure of Merit (FOM), where I use the the functional form

$$\text{FOM} = (v_1 - \alpha)^\beta \times \frac{v_1}{v_2}. \quad (2)$$

The values for α , β and the FOM cut offs shown in (4) were informed off a likelihood distribution created to minimise the weighted number of misclassification, where a misclassified QOP4 spectrum (99.9% confidence) was weighted ten times as much as a misclassified QOP3 spectrum (95% confidence), and so on for QOP2 spectra (signal present but unsure of type and/or redshift) and QOP1 (no confidence). I set parameters α , β and the FOM cutoff for each QOP as free variables in a Markov Chain Monte Carlo simulation, and then minimise the difference between AutoQOP and human assigned QOP. The approximate maximum likelihood of the marginalised distributions for this fit were selected as final values, such that $\alpha = 2.5$, $\beta = 0.75$ and the FOM boundaries are as given in (4).

$$\text{FOM} = (v_1 - 2.5)^{0.75} \times \frac{v_1}{v_2} \quad (3)$$

$$\text{QOP} = \begin{cases} 6 & \text{if FOM} > 4.5 \text{ and fit to a stellar template} \\ 4 & \text{if FOM} > 8.5 \\ 3 & \text{if FOM} > 4.5 \\ 2 & \text{if FOM} > 3 \\ 1 & \text{otherwise} \end{cases} \quad (4)$$

This suggested QOP is not meant to replace human quality flags, but simply give the redshifter an estimate of spectrum quality before and during manual verification of the automatic result. The probability of agreement with a human redshifter is illustrated in Figure 4. The suggested QOP is computed from first calculating a Figure of Merit (FOM) from the cross correlation results.

6. TEMPLATE SELECTION

It is common in automated matching systems to compare the input spectrum with a large number of templates. The templates found in MARZ were sourced from original templates from 2dF (Colless *et al.* 2001), WiggleZ (Drinkwater *et al.* 2010), the Gemini Deep Deep Survey Abraham *et al.* (2004), and AUTOZ (Baldry *et al.* 2014), where the templates in AUTOZ consist of galaxy eigenspectra from Bolton *et al.* (2012) and stellar spectra from SDSS DR2 (SubbaRao *et al.* 2002). These templates were sorted, compared, and a selection of twelve representative templates were extracted, consisting of 5 stellar templates, 1 AGN template and 6 galactic templates. Inclusion of a greater number of templates was found to have a minimal impact on matching performance. Whilst extra target types can be added in the future, there are three challenges for MARZ when attempting to handle a large number of templates. Firstly, users desired to be able to fully replicate the matching capacity of the automatic system when manually redshifting, and a large number of templates complicates the user interface and slows down the process of the user assigning an

Figure 5. A visual display of the twelve templates currently in MARZ, displayed after continuum subtraction.

Figure 6. A high quality emission line galaxy spectrum matched against the High Redshift Star Forming Galaxy template. The two strongest cross correlation peaks and the corresponding redshifted template have been displayed beneath the original spectrum for illustrative purposes.

object type to the spectrum. It would be possible to only display to the user a restricted set of templates, however user feedback indicated this was an undesired solution. Due to the interpreted nature of Javascript and its lack of vector processing capability, computational performance is roughly an order of magnitude worse than on typical compiled code. As the computation time for each spectrum was roughly proportional to the number of templates to match, the number of templates was also kept relatively small to ensure that the automatic matching performance was still acceptable on low-end machines. The final concern when adding more templates is the download size of the web application, such that the size of the template dependency remains small enough to be easily redownloaded on page refresh. A potential solution to this is to enable javascript caching of the template file, such that it only needs to be downloaded once.

7. MATCHING PERFORMANCE

Performance testing for MARZ was conducted by looking at two sets of distinct data - one from the OzDES team with low signal-to-noise data at high redshift, and one from the 2dFLenS team with medium signal-to-noise data. In both cases, manual redshifting was performed by experienced redshifters in RUNZ, and the automatic matches produced by RUNZ and the automatic results returned by MARZ were compared to the manually assigned redshift for all results assigned a QOP of 4. Comparisons were also made with the AUTOZ program, which is the software being used for the GAMA survey and also being adopted by the 2dFLenS team. These surveys have a smaller number of object types and smaller redshift ranges than OzDES, and therefore have simpler requirements for the redshifting software. These high and low signal-to-noise results are shown in Figures 7 and 8. The redshifting accuracy of MARZ for high signal-to-noise data gave the correct redshift for 97.4% of QOP4 spectra, a failure rate far less than that offered by RUNZ and comparable to AUTOZ. For the low signal-to-noise (high redshift) OzDES data,

Figure 7. A comparison of matching efficiency using high signal-to-noise data from the 2dFLenS survey and a matching threshold of $\Delta \log(1+z) \leq 0.0015$, corresponding to a velocity difference of 450 km/s. 2217 QOP4 spectra from ten fields are compared in this plot. The vertical axes shows the redshift assigned by an experienced redshifter, and is taken to be correct in this comparison. The horizontal axes show the automatic results of the four algorithms being compared: the RUNZ cross correlation algorithm, the RUNZ emission line matching algorithm, AUTOZ and MARZ. The success rate for each algorithm is shown in the top right of each subplot. The MARZ algorithm and AUTOZ offer comparable accuracy for high quality spectra, with AUTOZ pulling ahead slightly due to an increased number of templates being used in the matching process.

the accuracy of MARZ was 91.3%. This is in comparison to the best RUNZ algorithm giving a total accuracy of 54.6%. The lower success rate of AUTOZ, 48.0%, is because the redshift ranges and object types found in

Figure 8. Low signal-to-noise, high-redshift data from the OzDES survey is used in this comparison of matching capability, where two spectra agree if their recession velocity is within 450 km/s of each other for standard galactic templates, or within 900 km/s of each other for AGN spectra. Respectively this corresponds to $\Delta \log(1+z) < 0.0015$ and $\Delta \log(1+z) < 0.003$. AGN matches are shown with the + symbol, with other objects shown with a dot. Overall success rates are shown in the top right hand corner of each subplot. 1083 spectra from eight fields with a redshift range of up to 4.55 are used in this comparison. RUNZ emission line matching performs the worst, with strong diagonal lines of non-unity slope showing repeated spectrum feature misidentification. Vertical banding in the RUNZ cross correlation algorithm significantly impacts its effectiveness, and AUTOZ’s lack of high redshift templates and hard-coded $z = 0.9$ cutoff make the comparison almost inapplicable. We should also note in this comparison that RUNZ and MARZ were both run with template weighting enabled, giving them greater information than available to the AUTOZ algorithm. Given both these concerns, this plot should not be taken to show the algorithmic limits of the AUTOZ algorithm, it simply shows the success rate when run, without extra development or modification, against OzDES data. Here the quasar specific matching algorithm used by MARZ stands out, giving a success rate of over 90% for the OzDES spectra.

the OzDES data are outside the matching capacity of AUTOZ.

In addition to the QOP4 successful recovery rates, we can check for catastrophic matching failures ($\Delta \log(1+z) \geq 0.0075$) by creating a normalised probability distribution describing the likelihood for spectral line misclassification. This has been done for QOP4 and QOP3 results, in Figure 9. Commonly misidentified spectral lines are labeled in the figure, and can be seen to be a source of misclassification across all algorithms. The common [OII]/[OIII] misclassification is present in the MARZ failure rates, especially for the QOP3+QOP4 results, however it accounts for only approximately only one in four hundred misclassifications when comparing with QOP4 only data, and thus does not represent a significant issue with the matching algorithm. Commonly misclassified features are also visible on Figure 7 and 8 as linear relationships off the diagonal.

We checked MARZ for any systematic redshift offset by

comparing the redshift result obtained in MARZ against results obtained by using different, well tested software - RUNZ and AUTOZ. The redshift distribution found is shown in Figure 10. The mean and median redshift offset from MARZ (4×10^{-5} and 5×10^{-6} respectively) are comparable to the offsets found with AUTOZ, and do not show any sign of a systematic offset. The variance in redshift results found in MARZ ($\approx 3 \times 10^{-4}$) is also comparable to AUTOZ, and within the expected variance for AGN and galaxy targets (determined by repeated observation of the same target) of $\Delta z/(1+z) = 0.0015$ and $\Delta z/(1+z) = 0.0005$ respectively for the OzDES survey (Yuan *et al.* 2015). Due to the redshift variance between observations dominating any uncertainty in an individual match, MARZ does not assign uncertainty to redshift results. Instead, uncertainty will be determined based on object type and the results of repeated observations, which is detailed in Yuan *et al.* (2015, Table 4).

Figure 9. The percentage chance, per successfully assigned redshift of quality 3 or 4, of assigning an automatic redshift z_A categorised as a catastrophic failure with respect to correct manual redshift z_M (note that the manual redshift may be incorrect, and QOP4 spectra are those rated to be correct 99% percent of the time). QOP4 misclassifications are shown in solid colour, and total QOP4+QOP3 misclassifications are shown in the translucent bars. A catastrophic failure, here defined as $\Delta \log(1+z) > 0.0075$, corresponds to a velocity difference of 2250 km/s and generally indicates misclassified features in the spectra. For an analysis of non-catastrophic failures, see Figure 10. Peaks in the probability distribution generally represent misidentified spectral lines, and common misidentification ratios have had the corresponding spectral lines labelled, such that the first label, MgII/Hα represents the MgII feature misidentified as Hα instead. Performance for RUNZ cross correlation, RUNZ emission line matching, AUTOZ and MARZ are shown in their own panel. Panel probability axes are not to scale with one another, and the area covered represents the total failure rate. The 2dFlenS and OzDES data from Figures 7 and 8 are combined in this analysis to give the greatest number of data points. The catastrophic failure rates for QOP4 spectra are given as follows: RUNZ cross correlation: 37.4%, RUNZ emission line matching: 33.1% failure rate, AUTOZ: 19.4% failure rate, MARZ: 3.77% failure rate.

Figure 10. Systematic redshift offsets were investigated by examining the difference between manual redshifting (using the RUNZ cross correlation algorithm as the base) and the automatic results of redshifting algorithms. QOP4 spectra from OzDES and 2dFlenS were combined to give over three thousand secure manual redshifts, with the redshift distribution shown particularly for MARZ and AUTOZ. The mean offset and median for both algorithms is to the order of 10^{-5} or less, with the redshift variance on order 10^{-4} . The redshift mean and median values are small enough to be indicative that no systematic offset in redshift would be generated by utilising either algorithm.

8. INTERACTIVE INTERFACE

The interactive interface consists currently five primary screens: the overview, detailed, templates, settings, and usage screen. The first two screens - the overview and detailed screens, are where users will spend the vast majority of their time, and thus screenshots of them have been provided in Figures 11 and 12. The overview screen provides users with a high level view of the spectra in the loaded FITS file, detailing what they have been matched to and the quality assigned to the matches. Filtering for this screen allows users to sort results or to filter by categories, for example only displaying matches of quality (QOP) 4 or all matches to quasar templates. Matching results can be downloaded as comma-separated variable (CSV) files, and those same files can be used to load the matching results back into MARZ on different machines by simply dropping the results file into the program the same way as a user would load in a FITS file. This was added to allow easy verification of redshift results by different users on different machines. A progress bar at the top of the screen keep track of current file completion and file quality.

The detailed screen allows for better verification of automatic matches and also offers the possibility of manually redshifting spectra. Verification of the on screen displayed redshift is done simply by assigning a QOP value, and the top five automatic matches can be cycled if the best match is visibly incorrect. Keyboard shortcuts are available for almost all ac-

tions, where key mappings are based off the shortcuts available in RUNZ in order to make transitioning from RUNZ to the MARZ as easy as possible. Users can click on features in the detailed plot and then mark them as spectral lines. Matches can be updated by by automatically fitting to the best cross correlation peak value within a small deviation window. The user can also toggle whether to display the raw data or the preprocessed data, whether to render a template under the data plot, and whether to display continuum or not. Boxcar smoothing is available to help spectrum legibility.

The templates screen is mostly non-interactive, and simply displays all the templates used by the system with the option to enable or disable specific templates at will. The settings screen gives options to explicitly set how many processing threads to create, whether results should be saved in the background, and offers the ability to clear all saved results in the system, or to simply clear results for the currently loaded FITS. The usage page gives instructions on how to use the program, an explanation of the purpose of each screen, how to raise issues or feature requests via GitHub, and provides several example FITS files for users who simply want to test out the system without having to source a FITS file themselves. It also provides a list of keyboard shortcuts for those users whom are not familiar with RUNZ.

Two main error safeguards have been implemented in the program to stop unnecessary loss of work. The first is a confirmation request when attempting to close down the application, which solves the issue of closing the whole browser with an open tab of MARZ. The second and more robust solution is to use the local storage capacity available in modern browsers to save results in the background after every automatic or manual redshift is assigned. This allows users to close the program, and resume where they left off simply by dragging the original FITS file back into the application.

9. COMMAND LINE INTERFACE

A command line interface has also been developed for MARZ. It requires IO.js¹³ to be installed, and two IO.js dependencies are installed when running `install.sh -file-api`¹⁴ and JsDOM¹⁵. The run script `autoMarz.sh` takes a minimum single argument - the name of the FITS file to match. More detailed usage instructions and command line parameters are detailed in the project Github readme.¹⁶

10. CONCLUSION

Overall, it can be seen that for both high and low signal-to-noise data, MARZ outperforms RUNZ on automatic matching of spectra. MARZ also provides an enhanced and more intuitive user experience, and the web-based nature of the application means that installation and updating are now no longer of any concern

Figure 11. The overview screen, showing data from a FITS file courtesy of Chris Blake and the 2dFlenS survey. Users can switch between a sortable tabular view and a graphic tile view, filter on object types, redshift ranges, templates and QOP values. The top of the screen shows the navigation menu, file completion progress bar and input for user initials. Visible at the bottom of the screen is the application footer, which shows the program's progress through automatic matching (automatically matched templates are shown in red in the graphical tiles). The bar changes colour depending on progress - green for preprocessing, red for matching and blue for completed. During the first two stages, a pause button is available to the user. If any results exist, a download button is available, which saves the current results to the file system.

Figure 12. The detailed matching screen, showing spectrum 7 seen in the Overview screen in Figure 11. The menus at the top of the page allow the user to toggle data on or off (variance, templates and whether to use the raw data or processed data). The menu bar also allows the user to reset to automatic or manual results, smooth the data, select which template to compare against, toggle between the best five automatic results, change the visual offset of the template and manually set the displayed redshift. The user can mark spectral lines by selecting a feature in the plot (either in the main plot or in any callout window) and then select the desired transition (either via keyboard shortcut or by selecting an option in the bottom row of the menu). Users can also change redshift by clicking on peaks in the cross correlation graph found between the spectra plot and the menu bars. Quality values for redshifts can also be assigned via keyboard shortcuts or via the vertical button menu on the left, and assigning a quality saves the result in the background and moves to the next spectrum. In the case where the “QOP 0 only” option is selected in the left hand bar, the user is taken to the next spectrum without a quality flag set, or else it simply takes them to the next spectrum ordered by ID.

at all. As such, MARZ presents a strong alternative to the RUNZ application, and a large step forward in the demonstration of web frameworks as a platform for non-intensive computational analysis. As MARZ simply requires generic FITS files to work, it can be used for simple FITS file inspection or as a redshifting tool for other surveys.

ACKNOWLEDGEMENTS

We would like to thank the OzDES and 2dFlenS teams for their feedback, input and user testing. The MARZ template catalogue comes from the WiggleZ and SDSS template samples, and multiple external libraries have been utilised in the creation of this application: Google’s AngularJS, Twitter’s Bootstrap, AngularUI, Armit Kapadia’s fitsjs, Corban Brook’s Digital Signal Processing package, Eli Grey’s FileSaver.js, Tom Alexander’s regression.js package, lodash and jQuery. Parts of this research were conducted by the Australian Research Council Centre of Excellence for All-sky Astrophysics (CAASTRO), through project number CE110001020.
